## Halting problem undecidability and infinitely nested simulation (V2)

The halting theorem counter-examples present infinitely nested simulation (non-halting) behavior to every simulating halt decider. Whenever the pure simulation of the input to simulating halt decider H(x,y) never stops running unless H aborts its simulation H correctly aborts this simulation and returns H of root halting.

The pathological self-reference of the conventional halting problem proof counter-examples is overcome. The halt status of these examples is correctly determined. A simulating halt decider remains in pure simulation mode until after it determines that its input will never reach its final state. This eliminates the conventional feedback loop where the behavior of the halt decider effects the behavior of its input.

The x86utm operating system was created so that the halting problem could be examined concretely in the high level language of C. H is a function written in C that analyzes the x86 machine language execution trace of other functions written in C. H recognizes simple cases of infinite recursion and infinite loops. The conventional halting problem proof counterexample template is shown to simply be an input that does not halt.

H simulates its input with an x86 emulator until it determines that its input would never halt. As soon as H recognizes that its input would never halt it stops simulating this input and returns 0. For inputs that do halt H acts exactly as if it was an x86 emulator and simply runs its input to completion and then returns 1.

In theoretical computer science the random-access stored-program (RASP) machine model is an abstract machine used for the purposes of algorithm development and algorithm complexity theory. ...The RASP is closest of all the abstract models to the common notion of computer. <a href="https://en.wikipedia.org/wiki/Random-access stored-program machine">https://en.wikipedia.org/wiki/Random-access stored-program machine</a>

The C/x86 model of computation is known to be Turing equivalent on the basis that it maps to the RASP model for all computations having all of the memory that they need. As long as an C/x86 function is a pure function of its inputs the C/x86 model of computation can be relied upon as a much higher level of abstraction of the behavior of actual Turing machines.

This criteria merely relies on the fact that the UTM simulation of a machine description of a machine is computationally equivalent to the direct execution of this same machine:

#### halt decider (Olcott 2021)

A halt decider accepts or rejects inputs on the basis of the actual behavior specified by these inputs. Whenever the direct execution or pure simulation of an input would never reach its final state this input is correctly decided as not halting.

In computability theory, the halting problem is the problem of determining, from a description of an arbitrary computer program and an input, whether the program will finish running, or continue to run forever. <a href="https://en.wikipedia.org/wiki/Halting\_problem">https://en.wikipedia.org/wiki/Halting\_problem</a>

Because H only acts as a pure simulator of its input until after its halt status decision has been made it has no behavior that can possibly effect the behavior of its input.

**Pathological Input** to a halt decider is stipulated to mean any input that was defined to do the opposite of whatever its corresponding halt decider decides as Sipser describes:

Now we construct a new Turing machine D with H as a subroutine. This new TM calls H to determine what M does when the input to M is its own description  $\langle M \rangle$ . Once D has determined this information, it does the opposite. (Sipser:1997:165)

When D is invoked with input (D) we have pathological self-reference when D calls H with (D) and does the opposite of whatever H returns.

### Does D halt on its own machine description (D) ?

This question can only be correctly answered after the pathology has been removed. When a halt decider only acts as a pure simulator of its input until after its halt status decision is made there is no feedback loop of back channel communication between the halt decider and its input that can prevent a correct halt status decision. In this case the halt decider is only examining the behavior of the input and has no behavior that can effect the behavior of this input thus can ignore it own behavior.

The standard pseudo-code halting problem template "proved" that the halting problem could never be solved on the basis that neither value of true (halting) nor false (not halting) could be correctly returned from the halt decider to the confounding input.

```
// Simplified Linz(1990) A and Strachey(1965) P
void P(u32 x)
{
  if (H(x, x))
    HERE: goto HERE;
}
```

This problem is overcome on the basis that a simulating halt decider would abort the simulation of its input before ever returning any value to this input. It aborts the simulation of its input on the basis that its input specifies what is essentially infinite recursion (infinitely nested simulation) to any simulating halt decider.

Every input to a simulating halt decider that only stops running when its simulation is aborted unequivocally specifies a computation that never halts. When input to a simulating halt decider cannot possibly reach its final state then we know that this input never halts.  $(\neg \exists N \in Z + \text{ such that } H(x,y) \text{ simulates } N \text{ steps of } x(y) \text{ and } x \text{ stops running}) \vdash H(x,y) == 0$ 

### A simulating halt decider H divides all of its input into:

- (1) Those inputs that never halt unless H aborts their simulation (never halting). H aborts its simulation of these inputs an returns 0 for never halting.
- (2) Those inputs that halt while H remains a pure simulator (halting).

  H waits for its simulation of this input to complete and then returns 1 halting.

## Simulating partial halt decider H correctly decides that P(P) never halts (V1)

```
#include <stdint.h>
typedef void (*ptr)();
int H(ptr x, ptr y)
{
    x(y);
    return 1;
}

// Simplified Linz(1990) A
// and Strachey(1965) P
void P(ptr x)
{
    if (H(x, x))
        HERE: goto HERE;
}
int main(void)
{
    P(P);
}
```

A simulating halt decider acts as a pure simulator of its input until after its input halts on its own or the behavior of this input conclusively proves that it will never halt on its own.

For inputs that never halt on their own H does not return to its caller until after H has correctly matched non-halting behavior patterns such as infinite loop or infinite recursion.

This makes it impossible for a pathological input to thwart a correct halt status decision.

The pathological feedback loop between the halt decider and its input that otherwise makes inputs like the above impossible for H(P,P) to decide has been eliminated.

#### Halt decider theorem Olcott 2021

When-so-ever simulating halt decider H(X,Y) determines that the behavior of a pure simulation of its input correctly matches a infinite behavior pattern such that this input never stops running unless its simulation is aborted: H correctly aborts this input and returns 0.

H is a computable function that accepts or rejects inputs in its domain on the basis that the pure simulation of these inputs specify a sequence of configurations stop running without being aborted.

## X86 machine code and execution trace of {main, H, and P}

```
P()

## The direct execution of P(P) halts (V3)

The execution trace of the x86 emulation of P(P) by simulating halt decider H conclusively proves that P cannot possibly ever reach its final state of 0xc3f. This provides complete proof that that the input to H never halts thus H(P,P)==0 is correct.

P(P) is conditional only on whatever H(P,P) returns. H(P,P) is conditional only on whatever the simulation or execution of its input actually does. These are two entirely different conditions that result in entirely different behavior.

Here are the divergent execution sequences at the C level:

## int main(){ H(P,P); }

- (1) main()
- (2) calls H(P,P) that simulates the input to H(P,P)
- (3) that calls H(P,P) which aborts its simulation of P(P) and returns 0 to
- (4) main().

## int main(){ P(P); }

- (a) main() calls P(P) that
- (b) calls H(P,P) that simulates the input to H(P,P)
- (c) that calls H(P,P) which aborts its simulation of P(P) and returns 0 to
- (d) P(P) that returns to main()

# Peter Linz Ĥ applied to the Turing machine description of itself: (Ĥ)

The following simplifies the syntax for the definition of the Linz Turing machine  $\hat{H}$ , it is now a single machine with a single start state. A simulating halt decider is embedded at  $\hat{H}$ .qx. It has been annotated so that it only shows  $\hat{H}$  applied to  $\langle \hat{H} \rangle$ , converting the variables to constants.

 $\hat{H}$ .q0  $\langle \hat{H} \rangle \vdash^* \hat{H}$ .qx  $\langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}$ .qy  $\infty$  If the UTM simulation of the input to  $\hat{H}$ .qx  $\langle \hat{H} \rangle$  applied to  $\langle \hat{H} \rangle$  reaches its own final state.

## $\hat{H}$ .q0 $\langle \hat{H} \rangle \vdash^* \hat{H}$ .qx $\langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}$ .qn

If the pure simulation of the input to  $\hat{H}qx \langle \hat{H} \rangle \langle \hat{H} \rangle$  would never reach its final state (whether or not this simulation is aborted) then it is necessarily true that  $\hat{H}qx$  transitions to  $\hat{H}.qn$  correctly.

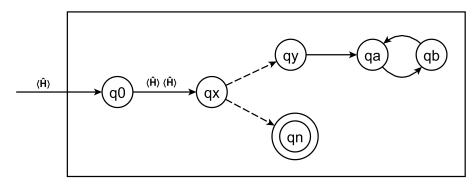

Figure 12.3 Turing Machine Ĥ applied to 〈Ĥ〉

 $\hat{H}$ .q0 copies its input  $\langle \hat{H}_0 \rangle$  to  $\langle \hat{H}_1 \rangle$  then  $\hat{H}$ .qx  $\langle \hat{H}_0 \rangle$   $\langle \hat{H}_1 \rangle$  simulates its input  $\hat{H}_0$ .q0 copies its input  $\langle \hat{H}_1 \rangle$  to  $\langle \hat{H}_2 \rangle$  then  $\hat{H}_0$ .qx  $\langle \hat{H}_1 \rangle$   $\langle \hat{H}_2 \rangle$  simulates its input.  $\hat{H}_1$ .q0 copies its input  $\langle \hat{H}_2 \rangle$  to  $\langle \hat{H}_3 \rangle$  then  $\hat{H}_1$ .qx  $\langle \hat{H}_2 \rangle$   $\langle \hat{H}_3 \rangle$  simulates its input.  $\hat{H}_2$ .q0 copies its input  $\langle \hat{H}_3 \rangle$  to  $\langle \hat{H}_4 \rangle$  then  $\hat{H}_2$ .qx  $\langle \hat{H}_3 \rangle$   $\langle \hat{H}_4 \rangle$  simulates its input.

 $\hat{H}$ .q0 copies its input  $\langle \hat{H}_0 \rangle$  to  $\langle \hat{H}_1 \rangle$  then  $\hat{H}$ .qx  $\langle \hat{H}_0 \rangle$   $\langle \hat{H}_1 \rangle$  simulates its input  $\hat{H}_0$ .q0 copies its input  $\langle \hat{H}_1 \rangle$  to  $\langle \hat{H}_2 \rangle$  then  $\hat{H}_0$ .qx  $\langle \hat{H}_1 \rangle$   $\langle \hat{H}_2 \rangle$   $\hat{H}$ .qx detects that a copy of itself is about to be simulated with a copy of its inputs.

If the simulating halt decider at  $\hat{H}$ .qx never aborts its simulation of its input this input never halts. If  $\hat{H}$ .qx aborts its simulation of its input this input never reaches its final state and thus never halts. In all cases for every simulating halt decider at  $\hat{H}$ .qx its input never halts.

When the pure simulation of the actual input to  $\hat{H}$ .qx  $\langle \hat{H} \rangle$  ( $\hat{H} \rangle$ ) never reaches the final state of this input then  $\hat{H}$ .qx transitions to  $\vdash^* \hat{H}$ .qn is necessarily correct no matter what  $\hat{H}$   $\langle \hat{H} \rangle$  does. A halt decider is only accountable for correctly deciding the halt status of its actual input.

When the original Linz H is applied to  $\langle \hat{H} \rangle$  it sees that its input transitions to  $\hat{H}$ .qn. This provides the basis for H to transition to its final state of H.qy.

When  $\hat{H}$ .qx is applied to  $\langle \hat{H} \rangle$  it sees that none of the recursive simulations of its input ever halt it aborts the simulation of its input and correctly transitions to its final state of  $\hat{H}$ .qn.

### The Peter Linz conclusion (Linz:1990:320)

Now  $\hat{H}$  is a Turing machine, so that it will have some description in  $\Sigma^*$ , say  $(\hat{H})$ . This string, in addition to being the description of  $\hat{H}$  can also be used as input string. We can therefore legitimately ask what would happen if  $\hat{H}$  is applied to  $(\hat{H})$ .

$$\hat{H}.q0 \langle \hat{H} \rangle \vdash^* \hat{H}.qx \langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}.qy \infty$$

if Ĥ applied to 〈Ĥ〉 halts, and

$$\hat{H}$$
.q0  $\langle \hat{H} \rangle \vdash^* \hat{H}$ .qx  $\langle \hat{H} \rangle \langle \hat{H} \rangle \vdash^* \hat{H}$ .qn

if  $\hat{H}$  applied to  $\langle \hat{H} \rangle$  does not halt. This is clearly nonsense. The contradiction tells us that our assumption of the existence of H, and hence the assumption of the decidability of the halting problem, must be false.

## My rebuttal to the Peter Linz Conclusion

This explicitly ignores the possibility that the input to  $\hat{H}$ .qx  $\langle \hat{H} \rangle$   $\langle \hat{H} \rangle$  never halts and  $\hat{H}$ transitions to  $\hat{H}$ .gn causing  $\hat{H}$  ( $\hat{H}$ ) to halt in exactly the same way that the input to H(P,P)never halts and H(P,P) returns 0 causing P(P) to halt.

A turing machine program consists of a list of 'quintuples', each one of which is a five-symbol turing machine instruction. For example, the quintuple 'SCcsm' is executed by the machine if it is in state 'S' and is reading the symbol 'C' on the tape. In that case, the instruction causes the machine to make a transition to state 's' and to overwrite the symbol 'C' on the tape with the symbol 'c'. The last operation it performs under this instruction is to move the tape reading head one symbol to the left or right according to whether 'm' is 'l' or 'r'. http://www.lns.mit.edu/~dsw/turing/doc/tm manual.txt

## **Glossary of Terms**

### computation

The sequence of configurations leading to a halt state will be called a computation. (Linz:1990:238)

### computation that halts

A Turing machine is said to halt whenever it reaches a configuration for which  $\delta$  is not defined; ... so the Turing machine will halt whenever it enters a final state. (Linz:1990:234)

#### computable function

Computable functions are the basic objects of study in computability theory. Computable functions are the formalized analogue of the intuitive notion of algorithms, in the sense that a function is computable if there exists an algorithm that can do the job of the function, i.e. given an input of the function domain it can return the corresponding output. https://en.wikipedia.org/wiki/Computable function

### computable function (Olcott 2021)

An algorithm is applied to an input deriving an output.

#### computer science decider

A decider is a machine that accepts or rejects inputs. https://cs.stackexchange.com/questions/84433/what-is-decider

### halt decider (Olcott 2021)

Function H maps finite string pairs (x,y) that specify a sequence of configurations to {0,1}

The input to H(x,y) is a finite string pair where x is a list of quintuples of Turing machine instructions and y is a finite string.

The formal proof of the behavior of N steps of x applied to y is the sequence of configurations derived when a UTM is applied to x on input y for N steps of configurations.

#### computer science decider

Intuitively, a decider should be a Turing machine that given an input, halts and either accepts or rejects, relaying its answer in one of many equivalent ways, such as halting at an ACCEPT or REJECT state, or leaving its answer on the output tape. https://cs.stackexchange.com/guestions/84433/what-is-decider

## [\*\*Halting problem undecidability and infinitely nested simulation V2\*\*]

(https://www.researchgate.net/publication/356105750\_Halting\_problem\_undecidability\_and\_infinitely\_nested\_simulation\_V2)

[Olcott 2021 generic halt deciding principle] Whenever the pure simulation of the input to simulating halt decider H(x,y) never stops running unless H aborts its simulation H correctly aborts this simulation and returns 0 for not halting.

If there is no N in the set of positive integers such that H(x,y) simulates N steps of x(y) and x stops running this proves H(x,y)==0.

## Strachey's Impossible Program

To the Editor, The Computer Journal.

### An impossible program

Sir.

A well-known piece of folk-lore among programmers holds that it is impossible to write a program which can examine any other program and tell, in every case, if it will terminate or get into a closed loop when it is run. I have never actually seen a proof of this in print, and though Alan Turing once gave me a verbal proof (in a railway carriage on the way to a Conference at the NPL in 1953), I unfortunately and promptly forgot the details. This left me with an uneasy feeling that the proof must be long or complicated, but in fact it is so short and simple that it may be of interest to casual readers. The version below uses CPL, but not in any essential way.

Suppose T[R] is a Boolean function taking a routine (or program) R with no formal or free variables as its argument and that for all R, T[R] — True if R terminates if run and that T[R] = False if R does not terminate. Consider the routine P defined as follows

rec routine P
 §L:if T[P] go to L
 Return §

If T[P] = True the routine P will loop, and it will only terminate if T[P] = False. In each case T[P] has exactly the wrong value, and this contradiction shows that the function T cannot exist.

Yours faithfully, C. STRACHEY.

Churchill College, Cambridge.
