## Author's Declaration

I hereby declare that I am the sole author of this thesis. This is a true copy of the thesis, including any required final revisions, as accepted by my examiners. I understand that my thesis may be made electronically available to the public.

#### Abstract

Recent studies show that when words are correlated with the colours they are printed in (e.g., MOVE is presented $75 \%$ of the time in blue), colour identification is faster when the word is presented in its expected colour (MOVE in blue) than in an unexpected colour (MOVE in green). The present series of experiments explored the possible mechanisms involved in this colourword contingency learning effect. Experiment 1 demonstrated that the effect was already present after 18 learning trials. During subsequent unlearning, the effect extinguished equally rapidly, suggesting that only a handful of the most recently encountered trials are used to predict responses. Two reanalyses of data from Schmidt, Crump, Cheesman, and Besner (2007) ruled out an account of the effect in terms of stimulus repetitions. Experiments 2 and 3 demonstrated that participants who carry a memory load do not show a contingency effect, supporting the hypothesis that limited-capacity resources are used to retrieve a small number of trial memories in order to prepare a response. Experiment 4 demonstrated that memory resources are required for both storage and retrieval processes.

## Acknowledgements

This research was supported by an NSERC Canada Graduate Scholarship. I thank Derek Besner and Jan De Houwer for their thoughtful comments on earlier versions of this thesis.

Correspondence concerning this thesis should be addressed to James R. Schmidt, Department of Psychology, University of Waterloo, 200 University Ave. W., Waterloo, Ontario N2L 3G1. Email: j4schmid@watarts.uwaterloo.ca.

## Introduction

The ability of humans to learn about contingencies between events in the world has recently re-appeared as a major topic in experimental psychology (e.g., Allan, 2005; Beckers, De Houwer, \& Matute, 2007; Mitchell, De Houwer, \& Lovibond, in press). Most often, contingency learning in humans is studied using paradigms in which participants see a series of situations in which stimuli or responses co-occur and are afterward asked to judge the strength of the contingency between the stimuli or responses. Other paradigms allow one to assess learning without asking participants to explicitly judge the strength of contingencies. One version of this is the colour-word contingency learning paradigm (Schmidt, Crump, Cheesman, \& Besner, 2007; see also Schmidt \& Besner, 2008; Musen \& Squire, 1993). For instance, Schmidt and colleagues presented four arbitrary words in four different display colours in a colour identification task using a key press response. As illustrated in Table 1, each word was presented in all colours, but more often in a particular colour (e.g., MOVE was presented $75 \%$ of the time in blue, SENT $75 \%$ of the time in green, etc.). Participants responded faster and made fewer errors on high contingency trials (where the word is presented in its correlated colour; e.g., MOVE blue ) than on low contingency trials (where the word is presented in any other colour; e.g., $\mathrm{MOVE}_{\text {green }}$ ). To date, little is known about how contingency information is actually learned in this paradigm. The present thesis briefly reviews past work, discusses several competing accounts, and reports four new experiments and two reanalyses of old data that provide new insights into the mechanisms underlying the form of contingency learning in this paradigm.

| Table 1. Example Contingency Mapping (75\%) |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: |
|  | MOVE | SENT | LIST | TELL |
| blue | 9 | 1 | 1 | 1 |
| green | 1 | 9 | 1 | 1 |
| yellow | 1 | 1 | 9 | 1 |
| orange | 1 | 1 | 1 | 9 |

There are several possible explanations for how contingency information is learned, but there are a few findings that narrow the field of potential explanations. For instance, awareness of contingency information in the paradigm used here does not seem to be necessary. Very few participants are aware of the contingency manipulation and the size of the colour-word contingency effect is unaffected by a participant's level of awareness (Schmidt et al., 2007, Experiment 3). Thus, awareness of contingencies does not seem to "buy" participants anything; the effect is the same size regardless. This suggests that, independent of the participant's awareness of the task manipulation, the processes involved in learning are implicit. A similar argument has been made from results of a flanker task in which flanking cues were predictive of the response (Carlson \& Flowers, 1996), sequence learning (Song, Howard Jr., \& Howard, 2007), and other paradigms (e.g., Lewicki, Hill, \& Czyzewska, 1992). However, the role of awareness in contingency learning is a highly controversial issue. In particular, there is little consensus on the proper way of assessing awareness and proponents of objective measures of awareness often argue for a small amount of awareness of learned information (e.g., see Fu, Fu, \& Dienes, 2007 for a detailed discussion of these issues). I simply note that, at the very least, the results of Schmidt and colleagues are difficult to reconcile with rule-based accounts that demand a role for conscious intention (although such rule-based processes may well play a role in unspeeded judgment tasks; e.g., see De Houwer, 2009; and Mitchell, De Houwer, \& Lovibond, in press for discussions of propositional accounts of associative learning). As a result, in the rest of the present thesis I narrow my focus to accounts that are more implicit in nature.

Another important finding of Schmidt and colleagues (2007, Experiment 4) is that the colour-word contingency effect does not simply reduce to stimulus-stimulus association or stimulus familiarity. In the critical experiment, two colours were assigned to the left key (e.g.,
blue and green) and two others were assigned to the right key (e.g., yellow and orange). If MOVE was presented most often in blue, then participants were faster to make the correct left key response to $\mathrm{MOVE}_{\text {blue }}$ and $\mathrm{MOVE}_{\text {green }}$ than they were to make right key responses to MOVE $_{\text {yellow }}$ and MOVE $_{\text {orange. }}$. Schmidt and colleagues observed no difference in responses to MOVE $_{\text {blue }}$ and MOVE $_{\text {green }}$. Thus, it is not the case that MOVE is associated with the colour blue (or else $\mathrm{MOVE}_{\text {green }}$ would not have been speeded), nor is it critical that participants saw the stimulus MOVE $_{\text {blue }}$ more often than the stimulus MOVE $_{\text {green }}$. Rather, it is critical that MOVE is associated with a left key response. When the correct response matches this associated response (for blue or green print), responding is facilitated. These results inform us that the learning mechanism is picking up on the contingencies between the distracting word and the response, not the contingencies between the distracting word and the target colour (however, it should be noted that effects of stimulus-stimulus associations have been observed in other paradigms; e.g., Colzato, Raffone, \& Hommel, 2006). Thus, I narrow my focus here to accounts that posit a relationship between the distracter and the response.

There are a number of accounts that could potentially explain the colour-word contingency effect. The simplest of these can be termed the repetition account, which explains the colour-word contingency effect in terms of transient memory effects. There are a few subtle variations of this. In one version, high contingency trials are speeded by the residual activation of the memory of recently encountered matching trials (Bertelson, 1961). For instance, high contingency trials such as MOVE $_{\text {blue }}$ would often be speeded because MOVE blue was recently encountered and the memory of this event is still active, allowing for a quicker response. In contrast, a low contingency trial such as MOVE $_{\text {green }}$ will rarely be speeded, because the probability of two instances of MOVE $_{\text {green }}$ occurring temporally close is much less likely.

According to a slightly different version of the repetition account, when a stimulus and response occur together the association between them is temporarily strengthened for a period of time. If the same stimulus and response are presented together shortly after this, responding will be facilitated. Again, high contingency trials are much more likely to have been recently preceded by the same word-response pairing (e.g., $\mathrm{MOVE}_{\text {blue }}$ before $\mathrm{MOVE}_{\text {blue }}$ ) than are low contingency trials (e.g., MOVE $_{\text {green }}$ before $\mathrm{MOVE}_{\text {green }}$ ).

Connectionist accounts such as the simple recurrent network (SRN; Cleeremans \& McClelland, 1991; Kinder \& Shanks, 2001, 2003) could explain the colour-word contingency effect in terms of a highly interconnected arrangement of nodes in which each trial causes the connection weights between nodes to change. For instance, presentation of $\mathrm{MOVE}_{\text {blue }}$ would lead to an increase in the connection strength between MOVE and the blue response (via a layer of hidden units) and a weakening of other connections (e.g., MOVE to the green response). The idea is that the system uses each trial to update the associations between stimuli and responses to gradually optimize performance by adapting to the statistical regularities in the task. Depending on the learning rates of the model, this process could happen relatively slowly or rapidly.

Finally, I consider a similar but conceptually distinct account based on the storage and retrieval of event files, the event file account. Hommel (1998) first introduced the notion of an event file as a temporary memory of an event that includes information about the stimuli presented along with the response that was executed. This idea is usually used to investigate the impact of trial transitions (i.e., whether the word and colour repeated, just one of the stimuli repeated, or both the word and colour alternated), but my suggestion is that these same event file memories could be used to generate response expectancies. According to this event file hypothesis (for a related account see Logan's, 1988 instance theory), participants in an
experiment store a memory of each encountered trial (event). Early processing of the word leads to retrieval of a set of the most recently encountered (i.e., most accessible) event files associated with this word (e.g., MOVE leads to retrieval of event files containing MOVE) and from these a response expectancy can be generated. As a result, high contingency trials will tend to be speeded because the system will be able to detect the contingencies in the task and prepare for the high contingency response. Note that the difference between this event file account and the repetition hypothesis is that the repetition hypothesis purports that individual recentlyencountered stimuli bias responding, whereas the event file hypothesis purports that several recently-encountered event files are retrieved and used to determine the likely outcome of the current trial.

As can be seen, there are a number of candidate explanations for the colour-word contingency effect. A number of important questions remain to be answered before the best account can be specified. For instance, we still do not have information about basic issues such as: (1) the number of trials needed to obtain the effect (i.e., acquisition speed), (2) whether and how fast the effect disappears when the contingencies are removed (i.e., extinction speed), and (3) whether contingency effects can be found only when sufficient memory resources are available. Just like studies of acquisition, extinction, and the effect of memory resources were crucial in developing theories about other forms of human contingency learning (e.g., De Houwer, 2009; De Houwer, Thomas, \& Baeyens, 2001; Shanks, 2007), examining these three issues in the context of the current contingency learning paradigm should provide important information about the processes underlying this effect. Experiment 1 addresses the first two questions and Experiments 2, 3, and 4 address the final question.

## Experiment 1

The rate of acquisition of contingency information is an important issue. For instance, if contingency information is both learned and unlearned rapidly, then this would pose a problem for a connectionist model with a low learning rate. It is already known that the colour-word contingency effect appears relatively early on in the course of an experiment. In a block analysis, Schmidt et al. (2007) found that the contingency effect was already significant in the very first block of 48 trials. The first goal of Experiment 1 is to increase the resolution of the block analysis by using smaller blocks of 18 trials. One possible outcome is that a contingency effect occurs very early on, perhaps in the first block of 18 trials, indicating that very few trials need to be experienced before contingency information can be extracted. Such a finding would be consistent with any model that is able to alter responding based on a limited sample of trials. This includes the repetition account, which explains the effect in terms of transient connections or activations and for connectionist accounts with a high learning rate. According to low learning rate connectionist accounts, however, acquisition should be slower and participants would need to accumulate experience with several blocks of trials before the effect emerges.

In an event file framework, understanding how fast a contingency is learned does not necessarily provide us with much information on how much data the system can take into account. For instance, imagine an event file account in which the system calculates the most likely response based on the identity of the word using the last 100 trials (a relatively large window) that it has encoded. Presumably, the system does not actually need 100 trials before it can start calculating; it can use whatever information it has accumulated so far (e.g., 12 instances if it is on trial 13). The system can use up to 100 trials, but does not necessarily need that many. In this sense, a rapid learning rate is not particularly diagnostic in discriminating between
accounts stating that the system can handle, for instance, 100 versus just 10 trials of information. As explained below, the unlearning manipulation reported here is much more informative in this respect.

The second goal of Experiment 1, therefore, is to investigate the rate of unlearning. Partway through the experiment, contingencies were suddenly and without notice switched from $67 \%$ (in a three-choice task) to $33 \%$ (chance; i.e., each word is presented equally often in all colours). The questions being investigated are whether the color-word contingency effect is eliminated, and if so, how fast? One possibility is that participants discover the statistical regularities early on in the task and stop searching for contingencies. If so, then the contingency effect should not be extinguished by changing the probabilities. More likely, the effect will extinguish, but the rate at which this happens is diagnostic for some of the competing accounts.

The repetition account assumes that the effect results from recent exposure to other similar trials and thus also predicts rapid unlearning. Similarly, a high learning rate connectionist account predicts, by definition, a high learning rate and fast extinction. In contrast, a low learning rate connectionist account predicts, by definition, a low learning rate and slow extinction, which would be reflected by a gradual decrease in the size of the contingency effect across several unlearning blocks.

For event file accounts, if the window of trials that participants retrieve for response prediction is large (e.g., the last 100 trials), then the contingency effect should very slowly extinguish as participants are exposed to more and more uncorrelated trials. This is because it will take a great deal of unlearning before the average contingency of the last 100 trials is substantially reduced (e.g., on the $21^{\text {st }}$ trial of unlearning, $80 \%$ of the trials the system is using are still from the learning phase). This slow unlearning would be reflected by a gradual decrease
in the size of the contingency effect across several unlearning blocks (just like the low learning rate connectionist prediction).

For an event file account that posits that the system relies on a limited number of the most recently encountered trials, the effect should extinguishing very rapidly, perhaps in the first block of changed probabilities. For instance, if the system makes its calculations based on just the last ten trials, then by trial 11 the participant is not using a single trial from the learning phase to generate response expectancies. Thus, for event file accounts, both a large window and small window version can accommodate fast learning, but only the small window account predicts fast extinction when unlearning.

In summary, Experiment 1 investigates the rate of initial learning of contingency information and subsequent unlearning. The experiment begins with three short blocks of 18 trials in which there is a $67 \%$ contingency. Learning across blocks is analysed to assess acquisition speed. Directly following these three learning blocks were nine unlearning blocks of 18 trials each in which the contingencies were dropped to chance ( $33 \%$, three choice). The decrease in the size of the contingency effect across unlearning blocks is assessed to determine extinction speed.

The repetition account predicts rapid learning and unlearning. For connectionist accounts, if the learning rate is high, then the contingency effect should emerge rapidly in learning and extinguish rapidly in unlearning. If the learning rate is low, then the contingency effect should emerge gradually in learning and extinguish gradually in unlearning. Finally, for event file accounts, learning could possibly occur rapidly regardless of window size. Unlearning speed will depend on the number of trials the system is able to use to generate response expectancies.

## Method

## Participants

Ninety-eight University of Waterloo undergraduates participated in Experiment 1 in exchange for course credit.

## Apparatus

Stimulus and response timing were controlled by E-Prime (Experimental Software Tools, 2002). Participants pressed the " j " key for blue, the " $k$ " key for red, and the " l " key for green with the first three fingers of their right hand.

## Materials and Design

Participants sat approximately 60 cm from the screen and viewed stimuli on a black screen. There were four stimulus words (LOCK, WIDE, REST, CRAM), but any given participant only saw three of these. ${ }^{1}$ There were three display colours (blue, red, green). The experiment began with three learning blocks of 18 trials each. In each learning block, each of the three words was presented four out of six times (67\%) in a randomly assigned colour (e.g., LOCK in blue, WIDE in red, REST in green) and once in each of the remaining colours (e.g., LOCK would be presented four times in blue, once in red, and once in green). Directly following these three learning blocks there were nine unlearning blocks, again of 18 trials each. In each unlearning block, each of the three words was now presented equally often (two out of six times) in each of the three colours. Participants were not notified of or told to expect the switch from learning to unlearning. Stimuli were presented in lowercase, bold, 18 pt. Courier New font. Stimuli within blocks were presented in random order.

## Procedure

At the beginning of each trial participants saw a white fixation cross for 250 ms , followed
by a blank screen for 250 ms , followed by the coloured word for 2000 ms or until a response was made. A blank screen was presented for 300 ms following a correct response, and the message "Incorrect" or "No response" was presented in red for 1000 ms following an incorrect or missed response, respectively.

## Results

Trials in which participants failed to respond were deleted from analyses (less than $1 \%$ of the data). For response latencies, only correct responses were analyzed. For each participant in each cell, response latencies that were more than 2.5 standard deviations above or below the mean were excluded from analysis (approximately $1 \%$ of the data). Other than reducing noise, these exclusion criteria do not affect the pattern of the results. ${ }^{2}$

## Response latencies

A 2 (contingency; high, low) x 12 (block) ANOVA for response latencies yielded a significant main effect of contingency, $F(1,97)=6.794, M S E=6112, p=.011$, a main effect of

| ** $\mathrm{p}<.004$ | oni co | ction) |  |  |

block, $F(11,1067)=3.179, M S E=11788, p<.001$, and an interaction, $F(11,1067)=4.736, M S E$ $=5647, p<.001$. Planned comparisons were conducted to determine which blocks yielded a significant contingency effect. The data and statistics are presented in Table 2. Comparisons revealed significant and relatively consistent contingency effects for all three learning blocks (Blocks 1-3). There was also a significant (but small) contingency effect in the first unlearning block immediately following learning (Block 4). For the following seven blocks (Blocks 5-11), there were no significant contingency effects and the differences were all close to zero. Unexpectedly, high contingency trials were significantly slower than low contingency trials in the final block (Block 12). However, given the number of statistical tests conducted and the fact that this difference is in the wrong direction for a contingency effect, this finding is likely a Type I error. Indeed, this effect is no longer significant after a Bonferroni correction (Block 4 falls below significance with this correction as well).

## Error percentages

The error data are presented in Table 3. A 2 (contingency) x 12 (block) ANOVA revealed

| Table 3. Experiment <br> Block and Contingency |  |  | Contingency |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | High | Low | Effect |  |  |
| Learning |  |  |  |  |  |
| Block 1 | 5.8 | 9.1 | 3.3 |  |  |
| Block 2 | 5.3 | 6.6 | 1.3 |  |  |
| Block 3 | 4.7 | 5.9 | 1.2 |  |  |
| Unlearning |  |  |  |  |  |

| Block 11 | 5.4 | 4.8 | -0.4 |  |  |
| Block 12 | 6.1 | 5.9 | -0.2 |  |  |

a significant main effect of block, $F(11,1067)=1.857, M S E=62, p=.041$, but no main effect of contingency, $F(1,97)=2.561, M S E=65, p=.113$, nor an interaction, $F(11,1067)=1.433, \operatorname{MSE}$ $=66, p=.152$. These data are not discussed further.

## Discussion

The results of this experiment clearly demonstrate that both learning and unlearning occur extremely rapidly. Initial contingency learning was significant in the very first block of 18 trials. It was initially my intention to study the time course of learning, but the learning slope is so sharp that detecting learning across blocks of this size is impossible. Unlearning seems to occur just as rapidly. There was only a very small carryover from the learning blocks into the first unlearning block, and then the effect disappeared in the following unlearning blocks. Thus, it is clear that the learning mechanism is highly responsive to the actual contingencies. This rules out a few of the accounts considered in the Introduction. The data are consistent with connectionist accounts, but only if a high learning rate is assumed. With a low learning rate, it would take the system much longer to accrue enough information to learn contingencies in the learning phase and it would take substantially more unlearning for the effect to extinguish. Similarly, the finding of rapid extinction rules out an event file account in which it is assumed that the system draws on a relatively large sample of trial memories. Fast learning and unlearning, however, is consistent with a small window event file account. Finally, the repetition account posits that the colour-word contingency effect results from transient repetition effects and is thus consistent with the observed rate of learning and unlearning.

## Reanalysis 1

The repetition account of the colour-word contingency effect, as noted above, attributes the effect to either residual activation or temporary SR associations occurring more often for high contingency trials than low contingency trials. The earliest experiments I conducted using the colour-word contingency paradigm had constraints on presentation order such that no colour could be repeated from one trial to the next, thus making it impossible for such complete repetitions (e.g., MOVE ${ }_{\text {blue }}$ could never directly follow MOVE $_{\text {blue }}$; Schmidt et al., 2007) and I have also been careful to control for $\mathrm{n}-1$ sequence effects wherever I had enough data per cell to do so (i.e., by deleting trials in which the colour repeats, thus eliminating complete repetitions, which are faster than other trials). Thus, I can already rule out an account that holds that colourword contingency learning results from trial $\mathrm{n}-1$ repetition effects. However, these controls have not ruled out sequence effects beyond trial $n-1$. For instance, it might be the case that complete repetitions on trial $n-2, n-3$, or perhaps even more distant lags also produce a speeding of responses. Thus, the contingency effect could simply be the result of the combination of benefits from various lags. I therefore conducted a reanalysis of data from Schmidt et al. (2007, Experiment 2) to test for $\mathrm{n}-2$ through $\mathrm{n}-5$ repetition effects. The critical test condition is complete repetitions, where both the word and colour repeat. I also coded for word repetitions, where the word but not the colour repeats; colour repetitions, where the colour but not the word repeats; and alternations, where neither the word nor colour repeats. The reason for selecting this particular experiment for my reanalysis is that the contingency manipulation was small enough ( $50 \%$ in a four choice task, where chance is $25 \%$ ) to allow sufficient observations in all cells (e.g., in experiments with high contingency manipulations where each low contingency pairing only occurs once per block, as was the case in Experiment 1 here, the
only way to get a complete repetition is for the last trial in one block to match the first trial in the next block).

The predictions of connectionist and event file accounts are less clear than those of the repetition account. One might argue that a connectionist model with a high enough learning rate should predict a larger influence of more recent trials (given that each new trial needs to be able to have a significant influence on connection weights). In that sense, repetition effects might be expected. However, even with high learning rates there is still an accumulation over several trials. For the event file account there is no a priori reason to expect that the most recent events should (or should not) have a greater influence on responding than later trials. The idea is that participants are retrieving a number of associated event files and determining the likely response based on these.

## Method

A full description of the methodology for the experiment used in this reanalysis can be found in the original article (Schmidt et al., 2007, Experiment 2). The study was very similar to Experiment 1 here. Participants were 16 University of Saskatchewan undergraduates. The task was four-choice rather than three. In each block, each of four words was presented 6 out of 12 times $(50 \%)$ in a randomly assigned colour and twice in the remaining colours in each of eight blocks. There was a constraint on presentation order such that the display colour could not repeat from one trial to the next. Trials were recoded for both contingency and for repetition type at four lags ( $n-2, n-3, n-4$, and $n-5$ ). Complete repetitions were trials in which both the word and colour repeated. Word repetitions were trials in which only the word repeated. Colour repetitions were trials in which only the colour repeated. Finally, alternations were trials in which neither the word nor the colour repeated.

## Results

There were very few errors in the experiment used for this and the following reanalysis (in fact, the average participant made about seven errors total, less than the number of conditions used in the following analyses). We therefore decided to restrict our analyses to response latencies. Trials on which participants failed to respond (less than $1 \%$ of the data) and incorrect responses (less than $4 \%$ of the data) were deleted. These trimming procedures do not alter the basic pattern of data reported below. The data are presented in Table 4.

Trial $n-2$

A 2 (contingency; high, low) x 4 (repetition type; complete repetition, word repetition, colour repetition, alternation) ANOVA for response latencies revealed a marginal main effect for

contingency, $F(1,15)=3.178, M S E=2587, p=.095$. Critically, there was no main effect of repetition type, $F(3,45)=1.871, M S E=2383, p=.148$, nor an interaction, $F(3,45)=1.453, M S E$ $=1453, p=.240$.

Trial $n-3$
A 2 (contingency; high, low) x 4 (repetition type; complete repetition, word repetition, colour repetition, alternation) ANOVA for response latencies revealed a significant main effect for contingency, $F(1,15)=8.624, M S E=3813, p=.010$. Again, there was no main effect of repetition type, $F(3,45)=.465, M S E=2905, p=.708$, nor an interaction, $F(3,45)=.375, M S E=$ $4504, p=.772$.

Trial $n-4$
A 2 (contingency; high, low) 4 (repetition type; complete repetition, word repetition, colour repetition, alternation) ANOVA for response latencies revealed a marginal main effect for contingency, $F(1,15)=3.180, M S E=7190, p=.095$. There was no main effect of repetition type, $F(3,45)=.006, M S E=6370, p=.999$, nor an interaction, $F(3,45)=.510, M S E=5669, p=$ . 677.

Trial $n-5$
A 2 (contingency; high, low) x 4 (repetition type; complete repetition, word repetition, colour repetition, alternation) ANOVA for response latencies revealed a significant main effect for contingency, $F(1,15)=5.128, M S E=2324, p=.039$. There was no main effect of repetition type, $F(3,45)=1.868, M S E=2499, p=.149$, nor an interaction, $F(3,45)=.070, M S E=2089, p$ $=.976$.

## Discussion

The results of Reanalysis 1 show no evidence for repetition effects at lags of two to five
trials. For each of these four lags, no effect of repetition type emerged. These null findings are problematic for the repetition account, which purports to explain the contingency effect solely by the influence of these transient repetition effects. Of course, interpreting the null is always difficult. One might argue that I merely lacked statistical power to detect these lag effects. However, there is a way to demonstrate that, in fact, lag effects do not explain the contingency effect. For this I turn to Reanalysis 2.

## Reanalysis 2

Reanalysis 1 indicated no evidence for $\mathrm{n}-2$ through $\mathrm{n}-5$ repetition effects. Rather than simply interpreting this null, I conduct a further analysis to demonstrate that these (absent) lag effects do not account for the contingency effect. Recall that the repetition account purports to fully explain the contingency effect in terms of these short-lived associations or activations. Thus, the argument is not only that there should be observable lag effects, but also that these lag effects should explain the variance attributed to the contingency effect. In other words, after accounting for the variance attributed to these lag effects, there should be no variance left over for the contingency manipulation to explain (i.e., because repetition effects are the contingency effect in this conceptualization). Thus, if the lag variables are entered into the first step of a regression analysis and then contingency is added to the model in a second step, then the new model with contingency included should not explain more variance. If more variance is explained by contingency, then this verifies that my initial analyses were not simply the result of poor statistical power. Instead, transient lag effects do not explain the contingency effect. The reader is again reminded that $\mathrm{n}-1$ repetition effects were controlled by design (i.e., colour repetitions were impossible), so only lags $n-2$ and beyond need to be entered into the regression.

## Method

The same data set used for Reanalysis 1 was used for Reanalysis 2. For this analysis, the full raw data set was dummy coded for participant, contingency, and the repetition type at each lag. That is, each individual trial for each participant was included as an observation in the regression and then participant number was included as a predictor in the regression along with contingency, repetition type, and lag (for an explanation of how to do regression with repeated
observations per participants see Bland \& Altman, 1995).

## Results

Null and incorrect responses were trimmed (as in the previous analysis). These trimming procedures do not alter the basic pattern of data reported below.

Step 1 - participant, repetition type, and lag
In Step 1 of the regression, the dummy coded variables for participants and for repetition trial types at the various lags were entered as predictors and response latency was entered as the outcome variable. Unsurprisingly, this model explained a significant amount of variance, $R^{2}=$ $.256, F(27,5896)=75.262, p<.001$. Note that this model explains the variance between participants (i.e., the multiple observations per participant were coded for participant number and instead of removing this variance, as in a traditional regression, between-participant variance was included as a predictor).

Step 2 - adding contingency
In Step 2 of the regression, all of the variables in Step 1 were included plus the new variable for contingency (high, low). The test for a change in the amount of variance explained was significant, $R^{2}$ Change $=.001, F$ Change $(1,5895)=11.018, p=.001$. Note that the reason for the small value of the $R^{2}$ Change is that the between participant differences account for an enormous chunk of the variation (accounted for in Step 1 of the regression). Within the full model, contingency accounts for 19 ms of variance.

## Discussion

The results of Reanalysis 2 corroborate the findings of Reanalysis 1 by showing that (the non-existent) repetition effects at lags of two to five trials do not explain the contingency effect. After putting all of these repetition variables into the first step of a regression to account for what
variation they could, contingency continued to explain variance in the second step of the regression. Note again that this experiment, by design, rules out $n-1$ repetition effects due to the constraint on presentation order (i.e., colour repetitions were impossible). As a result of this analysis, it is safe to conclude that the colour-word contingency effect reflects more than simple priming by transient activations or SR associations as posited by the repetition account, at least as far out as five trials.

The implication of these two reanalyses for connectionist and event file accounts is less certain. One might have expected some repetition effects at recent lags for a high learning rate connectionist account, but the argument probably cannot be made that such lag repetition effects should have completely accounted for the contingency effect. No strong prediction was made for the event file account.

## Experiment 2

Given how rapid learning and unlearning were in Experiment 1, it is clear that the "window" of trials that participants take into account when calculating their response prediction is remarkably small. This led me to the notion that participants may be using limited-capacity memory resources to retrieve a small number of recently encountered trials in preparing a response. This is consistent with the finding from the sequence learning literature that carrying a memory load impairs learning (Nissen \& Bullemer, 1987), though it is not clear that learning between trials is necessarily always the same as learning within trials (see the General Discussion for a discussion of the similarities and differences between the colour-word contingency paradigm and several other paradigms).

Experiment 2 tests this memory resource hypothesis by examining the impact of memory load on the color-word contingency effect. Participants in one condition were given a set of five digits to remember at the beginning of each trial and were tested for recognition at the end of each trial. Forcing participants to remember five digits should create a high load on memory, which leaves little or no memory resources to retrieve trial information that can be used to learn contingencies. Other participants were also presented with five digits, but were not instructed to remember them and were not probed for recognition. Thus, there is no load on memory, which ought to enable participants to use their memory resources for learning contingencies. Thus, a contingency effect is expected in the no load condition, where a smaller (or possibly null) effect is expected in the load condition.

## Method

## Participants

Thirty-nine University of Waterloo undergraduates participated in Experiment 2 in
exchange for course credit. None had participated in Experiment 1. Three participants were deleted from the load condition due to failing to achieve more than $70 \%$ accuracy on the memory task (see Results), leaving eighteen participants in each of the load and no load conditions.

## Apparatus

The apparatus for Experiment 2 was identical to Experiment 1 with one exception. In addition to the " j, " " k ," and " l " keys that were pressed with the right hand to respond to colours, participants in the load condition used their left hand to press the " $y$ " key for "yes" responses and the " $n$ " key for "no" responses in regard to the load manipulation.

## Materials and Design

The materials and design for Experiment 2 were identical to Experiment 1 with the following exceptions. There were only three stimulus words (LOCK, WIDE, REST). At the beginning of each trial, all participants were presented with a set of five random digits (0-9) horizontally presented with three spaces between each digit. Only participants in the load condition were presented with a second set of digits following a response to the target colour on each trial. For both groups of participants, there were two blocks of 60 trials each. In each block, a randomly selected digit in the memory set was changed to a new random digit on half of the trials and none of the digits changed on the other half of the trials. Orthogonal to this, each of the three words was presented eight out of ten times (80\%) in an assigned colour and once in each of the remaining colours (e.g., LOCK $80 \%$ in blue).

## Procedure

At the beginning of each trial participants saw a white fixation cross for 250 ms , followed by a digit memory set for 2000 ms . Participants in the load condition were instructed to remember these digits in order; participants in the no load condition were informed of the digits,
but were not asked to remember them. Next, there was a blank screen for 250 ms , followed by the coloured word for 2000 ms or until a response was made. The message "Correct," "Incorrect," or "No response" was presented in white for 500 ms following correct, incorrect, and null responses, respectively. For participants in the no load condition, the next trial started. For participants in the load condition, a second set of digits was presented until participants decided whether one of the digits had changed by pressing the " y " key (for "yes") or the "n" key (for "no"). This was followed by a second feedback screen, which was identical to the first (except that null responses were impossible).

## Results

The data of three participants in the load condition were deleted, two because of failure to achieve at least $70 \%$ accuracy on the memory task (indicating that they probably were not doing the secondary task) and one because their performance on the memory task was almost perfectly wrong (likely because they were responding on the basis of whether the digits had stayed the same, rather than whether they had changed). Null responses were deleted (less than $3 \%$ of the data), as were trials in which participants failed at the memory test in the load group (about $14 \%$ of the data). Because I was interested in trial n contingency effects and not sequential effects all trials where the word or colour was the same as that on the preceding trial were deleted. For response latencies, only correct responses were analyzed. In addition, for each participant in each cell, response latencies that were more than 2.5 standard deviations above or below the mean were excluded from analysis (approximately $2 \%$ of the data). With one exception (noted in a footnote below), these exclusion criteria do not alter the general pattern of the data.

| Table 5. Experiment 2 Response Latencies (in <br> milliseconds) for Contingency and Load |  |  |  |
| :--- | ---: | :---: | ---: |
|  | Contingency |  |  |
|  | High | Low | Effect |
| No Load | 649 | 738 | 89 |
| Load | 850 | 849 | -1 |

## Response latencies

The response latencies for Experiment 2 are presented in Table 5. A 2 (contingency; high, low) x 2 (memory load; load, no load) ANOVA for response latencies revealed a significant main effect of contingency, $F(1,34)=8.029, M S E=4395, p=.008$, a main effect of memory load, $F(1,34)=12.482, M S E=34944, p=.001$, and an interaction, $F(1,34)=8.354, M S E=$ $4395, p=.007$, in which there was a larger contingency effect for the no load group relative to the load group. Planned comparisons revealed that participants in the no load group responded faster to high contingency trials ( 649 ms ) than to low contingency trials ( 738 ms ), $t(17)=4.785$, $S E_{\text {diff }}=19, p<.001$. In contrast, participants in the load group did not respond faster to high contingency trials $(850 \mathrm{~ms})$ than to low contingency trials $(849 \mathrm{~ms}), t(17)=0.035, S E_{\text {diff }}=25, p$ $=.972 .^{2}$

## Error percentages

Percentage errors for Experiment 2 are presented in Table 6. A 2 (contingency) x 2 (memory load) ANOVA for error percentages revealed a marginal main effect of contingency, $F(1,34)=3.472, M S E=66, p=.071$, and a significant main effect of memory load, $F(1,34)=$ $6.283, M S E=119, p=.017$. The interaction was not significant, $F(1,34)=0.448, M S E=66, p=$

Table 6. Experiment 2 Percentage Errors for Contingency and Load

|  | Contingency |  |  |
| :--- | ---: | ---: | ---: |
|  | High | Low | Effect |
| No Load | 4.2 | 6.4 | 2.2 |
| Load | 9.3 | 14.2 | 4.9 |

.508. Planned comparisons revealed no significant differences in errors between high and low contingency trials for participants in the no load group (4.2 and $6.4 \%$, respectively), $t(17)=$ $2.278, S E_{\text {diff }}=2.2, p=.312$, and in the load group (9.3 and $\left.14.2 \%\right), t(17)=1.546, S E_{\text {diff }}=3.1, p=$ . 141.

## Discussion

The results of Experiment 2 demonstrate quite dramatically that the color-word contingency effect makes strong demands on memory. Participants put under a memory load did not show a contingency effect (or at least the effect was significantly attenuated), whereas those participants not put under a memory load did show a contingency effect. This is consistent with the idea that limited-capacity memory resources are required for colour-word contingency learning. Specifically, the argument is that when memory resources are taxed with a secondary task, there are no (or less) resources left over to store and/or retrieve event files that can be used to learn contingencies. The system requires memory resources to be free in order for event files to be stored and contingency information to be learned.

## Experiment 3

A potential problem with the methodology of Experiment 2 is that the trial sequence was somewhat different for participants in the load and no load conditions. For participants in the load condition, not only did they need to remember the digits presented at the beginning of the trial, but after responding to the print colour they were also presented with a second set of digits and were required to make a decision whether a digit had changed or not. It therefore may be the case that the disappearance of the contingency effect in the load condition of Experiment 2 was actually a result of the presentation of this second set of digits and/or the decision participants had to make in response to them. To address this concern, Experiment 3 uses a high load and low load condition to better equate the tasks.

## Method

## Participants

Sixty University of Waterloo undergraduates participated in Experiment 3 in exchange for course credit. None had participated in any of the previous experiments. Two participants were deleted from the high load condition and two from the low load condition for having less than $70 \%$ accuracy on the memory task, leaving twenty-eight participants in each of the high and low load conditions.

## Apparatus

The apparatus for Experiment 3 was identical to Experiment 2 in all respects.

## Materials and Design

The materials and design for Experiment 3 were identical to Experiment 2 with one exception. Instead of a load and no load group, participants were divided into a high and low load group. The high load group was identical in all respects to the load group of Experiment 2.

The low load group was identical in all respects to the high load group except that they were only given two, rather than five, digits to remember. Thus, with only two digits to remember, memory is not heavily loaded, leaving some memory resources for storing trial information to learn contingencies. As a result, a contingency effect is expected in the low load condition, but a small or null contingency effect is expected in the high load condition.

## Procedure

The procedure for both groups was identical in all respects to the procedure for the participants in the load group in Experiment 2.

## Results

The data of two participants in the high load condition and two in the low load condition were deleted because of less than $70 \%$ accuracy on the memory task. Null responses were deleted (less than 3\% of the data), as were trials in which participants failed on the memory test (about $11 \%$ and $8 \%$ of the data in the high and low load conditions, respectively). Because we were interested in trial $n$ contingency effects and not sequential effects all trials where the word or colour was the same as that on the preceding trial were deleted. For response latencies, only correct responses were analyzed. In addition, for each participant in each cell, response latencies that were more than 2.5 standard deviations above or below the mean were excluded from analysis (approximately $2 \%$ of the data). These trimming procedures do not alter the basic pattern of data reported below.

## Response latencies

The response latencies for Experiment 3 are presented in Table 7. A 2 (contingency; high, low) x 2 (memory load; high, low) ANOVA for response latencies yielded a significant main effect of contingency, $F(1,54)=16.921, M S E=7611, p<.001$, and an interaction, $F(1,54)=$

Table 7. Experiment 3 Response Latencies (in milliseconds) for Contingency and Load

|  | Contingency |  |  |
| :--- | ---: | ---: | ---: |
|  | High | Low | Effect |
| Low Load | 779 | 886 | 107 |
| High Load | 846 | 874 | 28 |

5.667, $M S E=7611, p=.021$, in which there was a larger contingency effect for the low relative to the high load group. The main effect of memory load was not significant, $F(1,54)=.453, M S E$ $=47878, p=.504$. Planned comparisons revealed that participants in the low load group responded faster to high contingency trials ( 779 ms ) than to low contingency trials $(886 \mathrm{~ms})$, $t(27)=4.055, S E_{\text {diff }}=26, p<.001$. In contrast, participants in the high load group did not respond significantly faster to high contingency trials ( 846 ms ) than to low contingency trials $(874 \mathrm{~ms}), t(27)=1.446, S E_{\text {diff }}=20, p=.160$.

## Error percentages

Percentage errors for Experiment 3 are presented in Table 8. A 2 (contingency) x 2 (memory load) ANOVA for error percentages was conducted. The main effect of contingency, $F(1,54)=.219, M S E=44, p=.642$, the main effect of memory load, $F(1,54)=1.263, M S E=72$, $p=.266$, and the interaction, $F(1,54)=.565, M S E=44, p=.455$, were not significant. Planned comparisons revealed no significant differences in errors between high and low contingency trials for participants in the low load group (4.5 and $4.1 \%$, respectively), $t(27)=0.216, S E_{\text {diff }}=$ $1.7, p=.830$, or in the high load group (5.4 and $6.9 \%), t(27)=.808, S E_{\text {diff }}=1.9, p=.426$.

Table 8. Experiment 3 Percentage Errors for Contingency and Load

|  | Contingency |  |  |
| :--- | ---: | ---: | ---: |
|  | High | Low | Effect |
| Low Load | 4.5 | 4.1 | -0.4 |
| High Load | 5.4 | 6.9 | 1.5 |

## Discussion

The results of Experiment 3 again demonstrate that the color-word contingency effect is dependent on limited-capacity memory resources. Participants put under a high memory load did not show a contingency effect (or at least the effect was significantly attenuated), whereas those participants put under a low memory load did show a contingency effect. These findings are consistent with the results of Experiment 2 using a (high) load versus no load manipulation.

## Experiment 4

The results of Experiment 3 leave several unanswered questions about the specific role of memory resources in contingency learning. One possibility is that memory resources are required for the binding of features and responses into event files. I term this the encoding hypothesis. That is to say, participants need memory resources in order to initially make and store event files. Thus, if memory resources are taxed by a difficult enough secondary task, then event files will not be created and there will, resultantly, be no event files (or perhaps incomplete event files) to retrieve to use to predict responses. If this view is correct, then it is not simply the case that participants are not showing a contingency effect while under load; rather, participants have not learned anything about the contingencies in the task.

A second possibility is that participants are able to create and store event files while under a memory load, but they are unable to retrieve these event files while under load. I term this the retrieval hypothesis. In this sense, participants put under memory load are learning contingency information, but are simply unable to use this learning in the presence of the secondary task.

A third possibility is that participants require memory resources both for the creation of event files and for the subsequent retrieval of event files. I term this the resource hypothesis. According to this hypothesis, memory resources are needed more broadly to carry out the various memory functions required for contingency learning. Thus, memory load, according to this hypothesis, impairs both storage and subsequent retrieval processes.

To test these various accounts, two groups of participants were tested in Experiment 4. Both groups underwent an initial Learning Block ( 36 trials) in which contingencies were introduced, followed by a Transfer Block (36 trials) in which contingencies were removed. The
critical test block in Experiment 4, as discussed below, is the Transfer Block. Note that although unlearning is rapid when contingencies are removed, transfer was observed in the initial unlearning block in Experiment 1. For Group 1, memory load was high for learning and low for transfer. For Group 2, memory load was low for learning and high for transfer. As described below, a control experiment was also run that was identical except that memory load was low for both learning and transfer.

If the encoding hypothesis is correct (i.e., memory resources are required for the creation of event files), then no contingency learning occurs under a high memory load. Thus, if the memory load is removed, no transfer of learning should occur. Thus, participants in Group 1 will not learn contingencies while under load in the Learning Block and should therefore not show any transfer in the Transfer Block. Alternatively, if the retrieval hypothesis is correct and participants are storing event files while under load in the Learning Block (but are simply not able to retrieve and use them while under load), then there should be a transfer of learning in the Transfer Block when the load is removed (i.e., a significant contingency effect). This latter result would constitute support for the retrieval hypothesis, by showing that learning can be achieved under load, but can only be applied once the load is removed (as evidenced by transfer). If memory resources are required for encoding and retrieval (the resource hypothesis), then no transfer should be observed.

If the retrieval hypothesis is correct, then event file contingency knowledge can only be used to predict responses when sufficient resources are available. Thus, if participants successfully learn contingencies under a low load, then none of this learning should transfer when a high load is introduced. Thus, participants in Group 2 who initially learned under low load should not be able to transfer learning into the high load Transfer Block because resources
are not available for retrieval. Alternatively, if the encoding hypothesis is correct and memory resources are only needed for initial encoding of event files, then transfer should be observed. In other words, according to the encoding hypothesis it does not matter if memory is currently loaded, so long as contingency information has been learned. Lastly, if memory resources are required for both binding and retrieval (the resource hypothesis), then no transfer should be observed (due to retrieval being impaired).

To summarize, the encoding hypothesis predicts that contingency effects will be observed when participants are not highly loaded while learning, thus predicting transfer in Group 2 but not in Group 1. The resource hypothesis predicts that contingency effects will be observed when participants are currently not highly loaded (i.e., when they are able to retrieve event files), thus predicting transfer in Group 1 but not in Group 2. Finally, the resource hypothesis predicts that both encoding and retrieval cannot be accomplished under load, thus predicting no transfer in either of the two groups. Given the latter possibility, a control experiment was also conducted to ensure that transfer can occur within the specific parameters used in this experiment. The control experiment was identical to the main experiment save for the fact that memory load was low in both the learning and transfer blocks.

As a final note, one could also argue that the load manipulation, rather than affecting limited-capacity resources, may be increasing noise in the stimulus representation. In other words, the claim is that the encoding of the main stimuli is "messier" when processing the additional load stimuli, thus making learning more difficult. I term this the messy encoding hypothesis. If this hypothesis true, then an effect on encoding should be expected. I can see no reason why such an account would also predict an effect of the secondary task on retrieval. As long as the contingencies were learned under low load (Group 2), presentation of the word
should be sufficient to retrieve the high contingency response, regardless of whether the system is currently loaded. Thus, the encoding hypothesis and messy encoding hypothesis make the same predictions.

## Method

## Participants

Eighty University of Waterloo undergraduates participated in Experiment 4 in exchange for course credit, with forty in each of the two groups. Seven participants in Group 1 and seven participants in Group 2 were deleted due to less than $70 \%$ accuracy on the memory task, leaving 33 participants per group. Another 33 participants from the same participant pool were in the control experiment. One participant was deleted due to less than $70 \%$ accuracy on the memory task, leaving 32 participants. None of the participants had participated in any of the previous experiments.

## Apparatus

The apparatus for Experiment 4 was identical to Experiment 2.

## Materials and Design

The materials and design for Experiment 4 were identical to Experiment 3 with the following exceptions. For both groups of participants, there were two blocks of 36 trials each. In the initial Learning Block, each of the three words was presented 8 out of 12 times (67\%) in an assigned colour and once in each of the remaining colours. In the subsequent Transfer Block, each of the three words was presented 4 out of 12 times in each colour ( $33 \%$, chance). Orthogonal to this, a randomly selected digit in the memory set was changed to a new random digit on half of the trials and none of the digits changed on the other half of the trials. For one group of participants (Group 1), load was high (five items) in the Learning Block and low (two
items) in the Transfer Block. For the other half of the participants (Group 2), load was low in the Learning Block and high in the Transfer Block. Participants were counterbalanced across groups. In the control experiment, load was low for both blocks. The critical question of interest is which groups of participants show transfer.

## Procedure

The procedure for Experiment 4 was identical in all respects to Experiment 3.

## Results

Trials on which participants failed to respond (less than $1 \%$ of the data) and trials on which participants made an error on the memory task (approximately $14 \%$ of the data) were removed. Correct response latencies were trimmed by removing trials for each participant in each cell that were over 2.5 standard deviations from the mean (less than $2 \%$ of the data). Seven participants in Group 1 and seven participants in Group 2 were deleted due to less than $70 \%$ accuracy on the memory task in the main experiment; one participant in the control experiment was removed from analyses based on the same criterion. These trimming procedures do not affect the basic pattern of results described below.

## Control: Low Load Learning - Low Load Transfer

Participants in the control experiment were given $67 \%$ contingencies to learn under low load in the Learning Block and then were presented with chance $33 \%$ contingencies under low load in the Transfer Block in order to ensure transfer was possible in the task.

Response latencies. Response latency data for the control experiment are presented in Table 9. A $t$-test on the Learning Block revealed that high contingency trials ( 891 ms ) were responded to significantly faster than low contingency trials $(930 \mathrm{~ms}), t(31)=2.759, S E_{\text {diff }}=14$, $p=.010$. Critically, a $t$-test on the Transfer Block revealed a significant transfer effect; high

Table 9. Experiment 4 Response Latencies (in milliseconds) for Group, Block, and Contingency

|  | Contingency |  |  |
| :--- | :---: | :---: | :---: |
|  | High | Low | Effect |
| Control |  |  |  |
| Learning Block (Low) | 891 | 930 | $39^{*}$ |
| Transfer Block (Low) | 788 | 815 | $27^{*}$ |
|  |  |  |  |
| Group 1 |  |  |  |
| $\quad$ Learning Block (High) | 1015 | 1032 | 17 |
| $\quad$ Transfer Block (Low) | 860 | 839 | -21 |
| Group 2 |  |  |  |
| $\quad$ Learning Block (Low) | 924 | 983 | $59^{*}$ |
| $\quad$ Transfer Block (High) | 900 | 897 | -3 |
| $* p<.05$ |  |  |  |

contingency trials ( 788 ms ) were responded to significantly faster than low contingency trials $(815 \mathrm{~ms}), t(31)=2.393, S E_{\text {diff }}=11, p=.023$. Thus, transfer can be observed in this version of the paradigm.

Percentage error. Percentage error data for the control experiment are presented in Table 10. A $t$-test on the Learning Block control data revealed that high contingency trials (3.8\%) did not generate significantly different errors than low contingency trials $(3.1 \%), t(31)=.532, S E_{\text {diff }}$ $=1.1, p=.599$. Additionally, a $t$-test on the Transfer Block revealed no significant difference between high contingency trials ( $3.1 \%$ ) and low contingency trials $(4.3 \%), t(31)=.847, S E_{\text {diff }}=$ $1.4, p=.403$.

## Group 1: High Load Learning - Low Load Transfer

The first group of participants were given $67 \%$ contingencies to learn under high load in the Learning Block and then were presented with chance $33 \%$ contingencies under low load in the Transfer Block in order to test the retrieval hypothesis. If participants need memory resources for retrieval, but not for encoding, then participants will encode contingency information in the Learning Block that they will retrieve in the Transfer Block where a transfer effect is expected.

| Table 10. Experiment 4 Percentage Errors for Group, <br> Block, and Contingency |  |  | Contingency |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
|  | High | Low | Effect |  |  |
| Control |  |  |  |  |  |
| Learning Block (Low) | 3.8 | 3.1 | -0.7 |  |  |
| Transfer Block (Low) | 3.1 | 4.3 | 1.2 |  |  |
|  |  |  |  |  |  |
| Group 1 |  |  |  |  |  |
| $\quad$ Learning Block (High) | 3.6 | 5.4 | 1.8 |  |  |
| $\quad$ Transfer Block (Low) | 2.2 | 2.8 | 0.6 |  |  |
| Group 2 |  |  |  |  |  |
| $\quad$ Learning Block (Low) | 2.6 | 7.4 | $4.8^{*}$ |  |  |
| $\quad$ Transfer Block (High) | 3.5 | 3.0 | -0.5 |  |  |
| * $p<.05$ |  |  |  |  |  |

Response latencies. Response latencies for Group 1 are presented in Table 9. At-test on the Learning Block revealed that high contingency trials ( 1015 ms ) were not responded to significantly faster than low contingency trials $(1032 \mathrm{~ms}), t(32)=.801, S E_{\text {diff }}=23, p=.429$. Critically, a $t$-test on the Transfer Block revealed no significant transfer effect; high contingency trials ( 860 ms ) were not responded to faster than low contingency trials $(839 \mathrm{~ms}), t(32)=1.131$, $S E_{\text {diff }}=19, p=.267$. Note that the numbers were numerically in the wrong direction. Thus, there was no evidence for the hypothesis that participants can learn under load.

Percentage error. The percentage error data for Group 1 and are presented in Table 10. A $t$-test on the Learning Block revealed that high contingency trials (3.6\%) did not generate significantly different errors than low contingency trials $(5.4 \%), t(32)=1.034, S E_{\text {diff }}=1.7, p=$ .309. Additionally, a $t$-test on the Transfer Block revealed no significant transfer effect; high contingency trials ( $2.2 \%$ ) did not generate significantly different errors than low contingency trials $(2.8 \%), t(32)=.717, S E_{\text {diff }}=0.9, p=.479$.

## Group 2: Low Load Learning - High Load Transfer

The second group of participants were given $67 \%$ contingencies to learn under low load
in the Learning Block and then were presented with chance $33 \%$ contingencies under high load in the Transfer Block in order to test the binding hypothesis. If participants need memory resources for encoding, but not for retrieval, then participants will show a transfer effect even though they are under high load (because the contingencies were encoded during initial low load learning).

Response latencies. Response latencies for Group 2 are presented in Table 9. A $t$-test on the Learning Block revealed that high contingency trials ( 924 ms ) were responded to significantly faster than low contingency trials $(983 \mathrm{~ms}), t(32)=3.013, S E_{\text {diff }}=20, p=.005$. Critically, a $t$-test on the Transfer Block revealed no significant transfer effect; high contingency trials ( 900 ms ) were not responded to faster than low contingency trials $(897 \mathrm{~ms}), t(32)=.159$, $S E_{d i f f}=18, p=.875$. Note that the numerical difference was again in the wrong direction. Thus, there was no evidence for the hypothesis that participants can retrieve and apply learning while under load.

Percentage error. The percentage error data are presented in Table 10. A $t$-test on the Learning Block revealed that high contingency trials (2.6\%) generated significantly less errors than low contingency trials $(7.4 \%), t(32)=2.916, S E_{\text {diff }}=1.6, p=.006$. Additionally, a $t$-test on the Transfer Block revealed no significant transfer effect; high contingency trials (3.5\%) did not generate significantly different errors than low contingency trials (3.0\%), $t(32)=.390, S E_{\text {diff }}=$ $1.2, p=.699$.

## Discussion

The results of Experiment 4 provide support for the resource hypothesis. Participants in Group 2 were not able to encode event files under high load, as indicated by the lack of transfer in the Transfer Block when the load was reduced. Further, participants in Group 1 were not able
to retrieve stored event files in the Transfer Block when put under high load. Data from the control experiment confirm that transfer is observable in this task setup. Thus, the combined results suggest that memory resources are required for both encoding and retrieval, in support of the resource hypothesis. These data are also inconsistent with the messy encoding account that proposed to explain the lack of a contingency effect under load as being due to noise in stimulus representation during encoding.

## General Discussion

The results of past work and the experiments and reanalyses presented here help to narrow the range of potential explanations for color-word contingency learning. The available data suggest that contingencies are acquired implicitly (Schmidt et al., 2007), that the critical contingency is between the word and the response (Schmidt et al., 2007), that learning and unlearning of contingencies is extremely rapid (Experiment 1), that the effect does not result from repetition effects (Reanalyses 1 and 2), and that contingency learning requires limitedcapacity memory resources (Experiments 2-4) for both storage and retrieval (Experiment 4). Given these criteria, we can begin to piece together a model of learning in this paradigm.

My favoured account of colour-word contingency learning assumes that participants use event files to represent contingency information. According to this event file hypothesis, on each trial a representation of the stimuli and response that was made are bound into an event file memory. These event files are then stored in an episodic store. On each trial, after the word is processed a number of matching event files are retrieved and a response expectancy is determined. For instance, as the participant processes the word MOVE, they will retrieve a number of event files that are associated with this (the most recently encountered ones being the most accessible) and use these to determine that blue is the most probable response. In a sense, this is a blending of Hommel's event file idea and Logan's (1988) instance theory.

The results of the experiments and reanalyses presented here are completely consistent with the event file account. The rapid learning of contingencies in Experiment 1 is consistent, because it will only take a handful of trials for participants to have been exposed to a number of high contingency pairings, while only seeing one or two low contingency pairings. Thus, right from the start, participants should be able to begin (implicitly) predicting responses. In addition,
because memory has a limited capacity and only so many event files can be retrieved, it will only take a small amount of unlearning before participants are no longer retrieving event files from the preceding learning phase (i.e., because the more-recently encountered unlearning trials are more accessible). As such, the rapid unlearning observed in Experiment 1 is also consistent with the event file hypothesis. Finally, the results of Experiments 2 though 4 are consistent with the event file hypothesis, because participants should require memory resources to carry out the memory functions required to store and subsequently retrieve event files, and memory load impairs these functions.

The rapid learning and unlearning of Experiment 1 are also consistent with the connectionist account, so long as the learning rate is assumed to be high. It is less clear that the connectionist account should predict the effects of memory load from Experiments 2 to 4, but presumably models such as the SRN can be easily modified to allow a role for limited-capacity resources in storage and retrieval processes. Note that the primary difference between the proposed event file hypothesis and connectionist models such as the SRN is the way in which learned information is represented. In the SRN, information is distributed across a network of hidden units. In the event file hypothesis, trial information is stored in discrete event files. Further research will need to be conducted to distinguish between these two possibilities.

Finally, I was able to rule out a repetition account in Reanalyses 1 and 2 by demonstrating that there were no lag effects that were able to explain the variance attributed to the contingency manipulation.

## Relation to Past Research

The colour-word contingency learning paradigm shares obvious similarities with numerous other cognitive paradigms. However, these paradigms also differ in a number of ways
from the paradigm used in the present studies, including the type of stimuli and responses that are involved in the task, the speed of judgment, and several other factors. Although commonalities surely exist, it remains to be seen which common processes underlie which effects of contingencies on performance. Until this issue is examined further, care should be taken when generalizing the conclusions from these studies to contingency learning in other paradigms (and vice versa). In the following sections I discuss the relation of the current paradigm to three other broad categories of paradigms: conflict paradigms (e.g., Stroop, Eriksen flanker), judgement tasks (e.g., evaluative conditioning, hidden covariation detection), and sequential learning.

Conflict Paradigms. The one paradigm that most of my colleagues seem to equate with the colour-word contingency learning paradigm is the Stroop task. Nonetheless, of the three types of paradigms discussed here, conflict paradigms such the Stroop task are arguably the least similar to the present contingency paradigm. On the surface, the colour-word contingency task is very similar to a Stroop task: participants are presented with coloured words and are asked to ignore the identity of the word and respond to the print colour. However, aside from this surface similarity, it can be argued that the two tasks are in fact quite different.

A Stroop task has no inherent contingency built into the task. In a properly designed Stroop task, each word should be presented equally often in each colour (unfortunately, this is rarely the case; see Schmidt \& Besner, 2008 for a discussion of why this is a problem). Instead, conflict paradigms such as the Stroop task are based on over-trained relations that are partially semantic in nature (e.g., De Houwer, 2003; Risko, Schmidt, \& Besner, 2006; Schmidt \& Cheesman, 2005). Although some may argue that colour words have an inherent contingency built into them (i.e., because the word BLUE is semantically related to the colour blue and the
blue response), it is doubtful that a semantic relationship is the same thing as a contingency, especially since Schmidt et al. (2007, Experiment 4) demonstrated that the contingency effect is purely response based, not semantic.

But perhaps the most convincing evidence that the effects observed in conflict paradigms are not the result of the same processes as the effects observed in our colour-word contingency task is the dissociation in the direction of the effects. Conflict paradigms, as the name suggests, generate interference-based effects. In the Stroop task, for instance, the difference in response latencies between congruent (e.g., BLUE $_{\text {blue }}$ ) and incongruent trials (e.g., BLUE green ) results almost entirely from the slowing of incongruent trials (relative to a baseline condition; e.g., MAKE $_{\text {green }}$ ). It is argued that this slowing results from competition between the distracting word and the target. Evidence for facilitation for congruent words is weak (see MacLeod, 1991 for a review). In our colour-word contingency paradigm, on the other hand, the response latency effect is entirely derived from facilitation of high contingency trials, with no corresponding interference for low contingency trials (Schmidt \& Besner, 2008). It has been argued that this facilitative effect results from the retrieval of event files in order to anticipate and prepare for the high contingency response (Schmidt \& Besner, 2008). Thus, not only is there a clear dissociation in the direction of the effects (interference in conflict paradigms versus facilitation in contingency learning), but it is also clear that the conceptualization of the mechanisms driving these effects is quite different (competition in conflict paradigms versus response preparation in contingency learning).

In summary, while conflict paradigms (especially Stroop) share many surface similarities with the colour-word contingency paradigm, they are arguably quite different. Conflict paradigms are based on over-trained relations, are partially semantic in nature, and are driven
almost entirely by interference. In contrast, colour-word contingency learning is based on newlytrained covariations, is non-semantic, and is driven entirely by facilitation. Thus, the informativeness of data from conflict paradigms for our contingency learning work is questionable.

Judgement Tasks. The colour-word contingency learning paradigm shares similarities with various judgement tasks. For instance, in the hidden covariation paradigm, participants learn the contingencies between facial characteristics and personality characteristics (Lewicki, 1985, 1986; Lewicki, Hill, \& Czyzewska, 1997; but see Hendrickx, De Houwer, Baeyens, Eelen, \& Van Avermaet, 1997a, 1997b). Similarly, in the evaluative conditioning paradigm participants’ liking of objects is altered by being paired with valenced words (see De Houwer et al., 2001 for a review). However, there are also many important differences. For instance, in these judgement paradigms the contingencies are typically $100 \%$ (e.g., in hidden covariation detection, Facial Characteristic X is always presented Personality Characteristic Y). In colour-word contingency learning, contingencies are less than chance. First, it is interesting that participants are able to detect a regularity in a noisy (i.e., non $100 \%$ contingency) dataset. Second, it is not certain whether detecting regularities in a noisy versus noiseless dataset involves identical processes (e.g., the latter case may lend itself more to explicit recognition of contingencies and be more prone to strategic influences).

Also, the colour-word contingency task involves speeded responses as the dependent measure, whereas judgement tasks such as evaluative conditioning most often involve a relatively slower judgment response (e.g., a judgement of the valence of an object). Changes in the rate of processing do not necessarily imply that the system will reach a different response. That is, just because a contingency may help to make a judgement faster, it does not follow that
the participant will necessarily be any more likely to make a given response (e.g., Stimulus B may cause a participant to select Response B regardless of whether they select the response quickly or slowly). Additionally, response latencies are sometimes used in these judgement tasks (e.g., Lewicki, 1986), but these judgment responses are overall much slower than rapid identification responses, so it remains unclear whether effects occurring in a few hundred milliseconds are simply a "scaled down" version of the effects occurring at a few thousand milliseconds. In particular, the relatively slower judgement responses may include more explicit (rather than implicit) processes.

Sequential Learning. Of all the paradigms discussed here, sequential learning may be the most similar to the colour-word contingency paradigm. In the typical sequential learning paradigm participants are presented with a series of target stimuli to respond to (no distracters) and the stimuli follow a predictive sequence (Nissen \& Bullemer, 1987). Most sequence learning research has participants respond to a sequence that is either random or $100 \%$ predictive (i.e., the same series of stimuli keep repeating). Learning is determined as the difference in response times between these two conditions. More similar to the colour-word contingency paradigm, some research with sequence learning has been done using probabilistic sequences (i.e., where the next item in the sequence is predictable, but not perfectly; Jimenez \& Mendez, 1999; Song et al., 2007).

In many ways, the colour-word contingency learning paradigm may seem redundant with the sequential learning paradigm, because both are speeded reaction time tasks that involve the learning of the relationship between stimuli and subsequent responses. However, the paradigms do differ in fundamental ways that may (or may not) prove significant. For instance, my paradigm involves participants retrieving trial memories on a trial-by-trial basis (i.e., participants
cannot know what response to expect until they have begun to process the word). In sharp contrast to this, in the sequence learning paradigm participants learn a long repeating series of stimuli and responses. This may result in strategic differences in learning and may also affect the rate of learning. Additionally, instead of learning the association of stimuli to responses, in sequence learning participants may be learning the series of responses (which is impossible in the colour-word contingency learning paradigm, because there is no response sequence).

Another fundamental difference between the contingency learning paradigm and the sequence learning paradigm is the type of information being retrieved. For colour-word contingency learning, participants retrieve individual events to determine what response is likely given the word. In contrast, for sequence learning participants must retrieve a series of events to determine what event is likely to follow. Put differently, if presentation of Stimulus A leads to retrieval of Memory $X$ (i.e., an event that contained Stimulus A), then participants will use Memory X to predict the response in my contingency learning paradigm, but would need to retrieve Memory $\mathrm{X}+1$ to predict the next item in sequence learning. What differences in learning this will lead to is unclear. More importantly, given these numerous fundamental differences, it cannot simply be assumed that every result found in sequence learning will also be found in colour-word contingency learning, or vice versa.

Summary. As I have highlighted, the colour-word contingency paradigm shares many similarities with other paradigms used to study contingency learning, but also has some differences. Thus, it appears premature to assume that an effect observed in one paradigm necessarily generalizes to the colour-word contingency paradigm (or vice versa). That said, there are some important ways in which the current results parallel findings from other contingency learning paradigms. Experiment 1 demonstrated extremely rapid learning of contingency
information. This finding is consistent with the rapid learning found in the hidden covariation detection paradigm, where response biasing has been demonstrated after exposure to as few as one or two consistent trials (Lewicki, 1985; Lewicki, 1986). In the sequence learning task, learning has been shown to take about seven blocks of a ten-trial sequence (Nissen \& Bullemer, 1987).

It is fascinating, however, that learning occurs so fast even in the colour-word contingency paradigm where contingencies are not $100 \%$. Rapid learning in a probabilistic task has also been reported by Jacoby, Lindsay, and Hessels (2003) using an item specific proportion congruent manipulation (which Schmidt \& Besner, 2008 have argued is simply a colour-word contingency effect incidentally observed within the context of a conflict paradigm). Although they did not provide individual $t$-tests for each block, visual inspection of their data suggests that a contingency effect was present in their very first block of 16 trials. Although there are not many studies on the learning rate in contingency learning paradigms (and I am not aware of any work on unlearning), it does appear that, in general, the human cognitive system is capable of very rapid learning (and unlearning) of covariations.

The results of Experiments 2 through 4 produced evidence that contingency learning in the colour-word paradigm is impaired when memory is loaded with a secondary task. Indeed, a similar result has been found in the sequence learning task, where minimal learning was found for participants under load (Nissen \& Bullemer, 1987). Although more work is certainly needed, it is interesting that apparently very simple learning processes that are generally reported to occur without awareness (e.g., Lewicki, 1986; Nissen \& Bullemer, 1987; Schmidt et al., 2007) seem to be dependent on the availability of memory resources (see Hassin, 2005 for a discussion of implicit working memory).

## Conclusions

The colour-word contingency paradigm is a useful tool to study contingency learning. It is very simple, easy to program, and produces highly reliable results. In the four experiments presented here it was discovered that learning and unlearning of contingencies in this paradigm is very rapid and is dependent on memory resources. Two reanalyses of old data ruled out a repetition account of these data. I have suggested that a viable explanation for these (and other findings) is that participants encode and subsequently retrieve a finite set of event files and use these event files to extract contingency information to be used to predict responses. Connectionist accounts such as the SRN could likely be modified to account for the current results, as well. The current results thus serve to constrain the types of viable accounts of contingency learning to those that are fast and those that require a role for limited-capacity memory resources.

## Footnotes

${ }^{1}$ This was a programming error. Four words (rather than three) were randomly assigned to an array of size four for each participant. The program only needed three words and only referenced the first three positions of this array. Thus, whichever word was assigned to the forth position of the array for a given participant was simply never referenced and never presented to the participant. Note that this in no way confounds my results.
${ }^{2}$ Unlike Experiments 2 and 3 to follow, immediate repetition trials were not trimmed in this experiment (i.e., trials in which the preceding trial had the same word and/or colour). The reason that this is a particularly important trimming procedure is because complete repetition trials (i.e., trials in which both the word and the colour are repeated) are responded to very quickly and these trials are disproportionately represented in the high contingency condition. In fact, due to the blocked structure of the task, the only way it is possible to have a complete repetition in the low contingency condition is for the last trial of one block to match the first trial of the next block. I opted not to perform this trimming procedure in Experiment 1 for two reasons. First, there were already so few observations per cell (in fact, only 10 of the 98 participants had an observation left in every cell after this trim). Second, sequential effects do not confound analyses in the unlearning blocks, given that complete repetitions are no longer disproportionately represented in the high contingency cells. Moreover, analyses with repetition trials removed yield similar (howbeit substantially noisier) results. The same is true of Experiment 4.
${ }^{3}$ If the confounded repetition trials are not removed, this effect is significant, but still significantly smaller than the effect for the load participants.
